Abstract

Generative models for source code are an interesting structured prediction problem, requiring to reason about both hard syntactic and semantic constraints as well as about natural, likely programs. We present a novel model for this problem that uses a graph to represent the intermediate state of the generated output. The generative procedure interleaves grammar-driven expansion steps with graph augmentation and neural message passing steps. An experimental evaluation shows that our new model can generate semantically meaningful expressions, outperforming a range of strong baselines.

1 Introduction

Learning to understand and generate programs is an important building block for procedural artificial intelligence and more intelligent software engineering tools. It is also an interesting task in the research of structured prediction methods: while imbued with formal semantics and strict syntactic rules, *natural* source code carries aspects of natural languages, since it acts as a means of communicating intent among developers. Early works in the area have shown that approaches from natural language processing can be applied successfully to source code [12], whereas the programming languages community has shown great successes in focusing exclusively on formal semantics. More recently, methods handling both modalities (*i.e.*, the formal and natural language aspects) have shown successes on important software engineering tasks [3, 5, 21].

However, current *generative* models of source code still focus on only one of these modalities at a time. For example, program synthesis tools based on enumeration and deduction [8, 9, 18, 23] are successful at generating programs that satisfy some (usually incomplete) formal specification but are often obviously wrong on manual inspection, as they cannot distinguish unlikely from likely, "natural" programs. On the other hand, (neural) generative code models have become successful at generating realistic-looking programs [16, 17, 19, 24] that often fail to be semantically relevant (or even have any semantics, in the case of syntax or typing errors).

In this work, we try to overcome these challenges for generative code models. We present a general method for building generative models of structured objects that allows us to incorporate structured information that is deterministically available at generation time. We focus our attention on generating source code and follow the ideas of *program graphs* [3] that have been shown to learn semantically meaningful representations of (pre-existing) programs. To achieve this, we lift standard grammar-based tree decoder models into the graph setting, where the diverse relationships between various elements of the generated code can be modeled. For this, the syntax tree under generation

Algorithm 1 Pseudocode for Expand

```
Input: Context c, partial AST a, node v to expand

1: \mathbf{h}_v \leftarrow \mathsf{getRepresentation}(c, a, v)

2: rhs \leftarrow \mathsf{pickProduction}(v, \mathbf{h}_v)

3: \mathbf{for} child node type \ell \in rhs \mathbf{do}

4: (a, u) \leftarrow \mathsf{insertChild}(a, \ell)

5: \mathbf{if} \ \ell is nonterminal type \mathbf{then}

6: a \leftarrow \mathsf{Expand}(c, a, u)

7: \mathbf{return} \ a
```

Figure 1: Example for ExprGen, target expression to be generated is marked. Taken from BenchmarkDotNet, lightly edited for formatting.

is deterministically augmented with additional edges denoting known relationships (e.g., last use of variables). We then interleave the steps of the generative procedure with neural message passing [10] to compute more precise representations of the intermediate states of the program generation. This is fundamentally different from sequential generative models of graphs [15, 22], which aim to generate all edges and nodes, whereas our graphs are deterministic augmentations of generated trees.

To summarize, we present a) a general graph-based generative procedure for highly structured objects, incorporating rich structural information; b) ExprGen, a new code generation task focused on generating small, but semantically complex expressions conditioned on source code context; and c) a comprehensive experimental evaluation of our generative procedure and a range of baseline methods from the literature.

2 Background & Task

The most general form of the code generation task is to produce a (usually small) program in a programming language given some context information c. This context information can be natural language (as in, e.g., semantic parsing), input-output examples (e.g., inductive program synthesis), partial program sketches, etc. Early methods used natural language processing techniques to generate source code as a sequence of tokens [11, 12], which often fail to produce syntactically correct code. More recent models are sidestepping this issue by using the target language's grammar to generate abstract syntax trees (ASTs) [16, 17, 19, 24], which are syntactically correct by construction.

In this work, we follow the AST generation approach. The key idea is to construct the AST a sequentially, by expanding one node at a time using production rules from the underlying programming language grammar. This simplifies the code generation task to a sequence of classification problems, in which an appropriate production rule has to be chosen based on the context information and the partial AST generated so far. In this work, we simplify the problem further by fixing the order of the sequence to always expand the left-most, bottom-most nonterminal node. Alg. 1 illustrates the common structure of AST-generating models [16, 19, 24]. Then, the probability of generating a given AST a given some context c is

$$p(a \mid c) = \prod_{t} p(a_t \mid c, a_{< t}),$$
 (1)

where a_t is the production choice at step t and $a_{< t}$ the partial syntax tree generated before step t.

Code Generation as Hole Completion We introduce the ExprGen task of filling in code within a hole of an otherwise existing program. This is similar, but not identical to the auto-completion function in the editor, as we assume information about the following code as well and aim to generate whole expressions rather than single tokens. The ExprGen task also resembles program sketching [23] but we give no other (formal) specification other than the surrounding code. Concretely, we restrict ourselves to expressions that have Boolean, arithmetic or string type, or arrays of such types, excluding expressions of other types or expressions that use project-specific APIs. An example is shown in Fig. 1. We picked this subset because it already has rich semantics that can require reasoning about the interplay of different variables, while it still only relies on few operators and does not require to solve the problem of open vocabularies of full programs, where an unbounded number of methods would need to be considered.

In our setting, the context c is the pre-existing code around a hole for which we want to generate an expression. This also includes the set of variables v_1, \ldots, v_ℓ that are in scope at this point, which can be used to guide the decoding procedure [16]. Note, however, that our method is *not* restricted to code generation and can be easily extended to all other tasks and domains that can be captured by variations of Alg. 1 (e.g. in NLP).

3 Graph Decoding for Source Code

To tackle the code generation task presented in the previous section, we have to make two design choices: (a) we need to find a way to encode the code context c, v_1, \ldots, v_ℓ and (b) we need to construct a model that can learn $p(a_t \mid c, a_{< t})$ well. We do *not* investigate the question of encoding the context in this paper, and use two existing methods in our experiments in Sect. 5. Each of these encoders yields a distributed vector representation for the context and for each of the variables v_1, \ldots, v_ℓ . This information can then be used in the generation process, which is the main contribution of our work and is described in this section.

Overview Our decoder model follows the grammar-driven AST generation strategy of prior work as shown in Alg. 1. The core difference is in how we compute the representation of the node to expand. Maddison and Tarlow [16] construct it entirely from the representation of its parent in the AST. Rabinovich et al. [19] construct the representation of a node using the parents of the AST node but also found it helpful to take the relationship to the parent node (*e.g.* "condition of a while") into account. Yin and Neubig [24] on the other hand propose to take the last expansion step into account, which may have finished a subtree "to the left". In practice, these additional relationships are usually encoded by using gated recurrent units with varying input sizes.

We propose to generalize and unify these ideas using a graph to structure the flow of information in the model. Concretely, we use a variation of attribute grammars [13] from compiler theory to derive the structure of this graph. Below, we explain the details of our model. The reader may notice that although we discuss our model in terms of code generation, the ideas can be easily applied to the generation of other structured objects with deterministic constraints in their structure.

We associate each node in the AST with two fresh nodes representing *inherited* resp. *synthesized* information (or attributes). Inherited information is derived from the context and parts of the AST that are already generated, whereas synthesized information can be viewed as a "summary" of a subtree. In classical compiler theory, inherited attributes usually contain information such as declared variables and their types (to allow the compiler to check that only declared variables are used), whereas synthesized attributes carry information about a subtree "to the right" (*e.g.*, which variables have been declared). Traditionally, to implement this, the language grammar has to be extended with explicit rules for deriving and synthesizing attributes.

To transfer this idea to the deep learning domain, we represent attributes by distributed vector representations and train neural networks to learn how to compute attributes. Our method for getRepresentation from Alg. 1 thus factors into two parts: a deterministic procedure that turns a partial AST $a_{< t}$ into a graph by adding additional edges that encode attribute relationships, and a graph neural network that learns from this graph.

Example Consider the AST of the expression i - j shown in Fig. 2 (annotated with attribute relationships). The AST derivation using the programming language grammar is indicated by thin black lines; nonterminal nodes are shown as rectangles, and terminal nodes are shown as rectangles. We additionally show the variables given within the context below the dashed line. First, the root node, Expr, was expanded using the production rule $(2) : \text{Expr} \Longrightarrow \text{Expr} - \text{Expr}$. Then, its two nonterminal children were in turn expanded to the set of known variables using the production rule $(1) : \text{Expr} \Longrightarrow \mathcal{V}$, where we have chosen i for the first variable and j for the second variable (cf) below for details on picking variables).

Attribute nodes are shown next to their corresponding AST nodes. For example, the root node is associated with its inherited attributes node 0 and with node 10 for its synthesized attributes. As a simplification, we use the same representation for inherited and synthesized attributes of terminal nodes (*i.e.*, tokens in the program text).

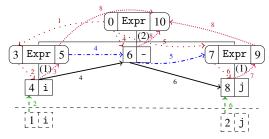

Figure 2: Example AST with attribute dependencies. Each AST node (labeled by a terminal or non-terminal) has either one or two associated attribute nodes, shown to the left/right of the label. Edge style/color indicates edge type and edge labels indicate the order in which edges are used.

Algorithm 2 Pseudocode for ComputeEdge

```
Input: Partial AST a, node v
 1: \mathcal{E} \leftarrow \emptyset
 2: if v is inherited then
 3:
          \mathcal{E} \leftarrow \mathcal{E} \cup \{(\mathsf{parent}(a, v), \mathit{Child}, v)\}
          if v is terminal node then
 4:
 5:
              \mathcal{E} \leftarrow \mathcal{E} \cup \{(\mathsf{lastToken}(a, v), NextToken, v)\}
              if v is variable then
 6:
 7:
                  \mathcal{E} \leftarrow \mathcal{E} \cup \{(\mathsf{lastUse}(a, v), NextUse, v)\}
 8:
          if v is not first child then
 9:
              \mathcal{E} \leftarrow \mathcal{E} \cup \{(\mathsf{lastSibling}(a, v), NextSib, v)\}
10: else
11:
           \mathcal{E} \leftarrow \mathcal{E} \cup \{(u, Parent, v) \mid u \in \mathsf{children}(a, v)\}
           \mathcal{E} \leftarrow \mathcal{E} \cup \{(\mathsf{inheritedAttr}(v), \mathit{InhToSyn}, v)\}
12:
13: return \mathcal{E}
```

We discuss the edges used in our *neural attribute grammars* (NAG) on an example below, and show a precise definition in Alg. 2.

Edges in $a_{< t}$ The edges in Fig. 2 represent the flow of information, where different edges are drawn with different styles to indicate different edge types. Once a node is generated, the edges connecting this node can be deterministically added to $a_{< t}$, following algorithm Alg. 2. The intuition of different edges is as follows:

- *Child* (red loosely dotted) edges connect an inherited attribute node to the inherited attributes nodes of its children, as seen in the edges from node 0. These are the connections in standard syntax-driven decoders [16, 17, 19, 24].
- Parent (purple densely dotted) edges connect a synthesized attribute node to the synthesized attribute node of its AST parent, as seen in the edges leading to node 10. These are the additional connections used by the R3NN decoder introduced by Parisotto et al. [17].
- NextSib (blue dash-dotted) edges connect the synthesized attribute node to the inherited attribute node of its next sibling on the right (e.g. from node 5 to node 6). This allows information about the synthesized attribute nodes from a fully generated subtree to flow to the next subtree.
- NextUse (green dashed) edges connect the attribute nodes of a variable (since variables are always terminal nodes, we do not distinguish inherited from synthesized attributes) to their next use. This can create edges from nodes of variables in the context c (for example, from node 1 to 4 in Fig. 2), or can connect AST leaf nodes that represent multiple uses of the same variable within the generated expressions.
- NextToken (thick black) edges connect a terminal node (a token) to the next token in the program text, for example between nodes 4 and 6.
- InhToSyn edges (not shown in Fig. 2) connect the inherited attributes nodes to its synthesized attribute nodes. This is not strictly adding any information, but we found it to help with training.

The edge labels in Fig. 2 indicate the timestep at which the representation of an attribute node can be computed. For example, in the second step, the attributes for the terminal token i (node 4) in Fig. 2 are computed from the inherited attributes of its AST parent Expr (node 3), the attributes of the last use of the variable i (node 1), and the node label i. In the third step, this computed attribute is used to compute the synthesized attributes of its AST parent Expr (node 5).

Attribute Node Representations To compute the neural attribute representation \mathbf{h}_v of an attribute node v whose corresponding AST node is labeled with ℓ_v , we first obtain its incoming edges using Alg. 2 and then use the state update function from Gated Graph Neural Networks (GGNN) [14]. Thus, we take the attribute representations \mathbf{h}_{u_i} at edge sources u_i , transform them according to the

corresponding edge type t_i using a learned function f_{t_i} , aggregate them (by summing them) and combine them with the learned representation $emb(\ell_v)$ of the node label ℓ_v using another learned function q:

$$\mathbf{h}_v = g(\mathsf{emb}(\ell_v), \sum_{(u_i, t_i, v) \in \mathcal{E}_v} f_{t_i}(\mathbf{h}_{u_i})) \tag{2}$$

In practice, we use a single linear layer for f_{t_i} and implement g as a gated recurrent unit [7]. We compute node representations in such an order that all \mathbf{h}_{u_i} appearing on the right of (2) are already computed. This is possible as the graphs obtained by repeated application of Alg. 2 are directed acyclic graphs rooted in the inherited attribute node of the root node of the AST. We initialize the representation of the root inherited attribute to the representation returned by the encoder for the context information.

Choosing Productions & Variables We can treat picking production rules as a simple classification problem over all valid production rules, masking out those choices that do not correspond to the currently considered nonterminal. For a nonterminal node v with label ℓ_v and inherited attributes \mathbf{h}_v , we thus define

$$\mathsf{pickProduction}(\ell_v, \mathbf{h}_v) = \arg\max P(rule \mid \ell_v, \mathbf{h}_v) = \arg\max \left[e(\mathbf{h}_v) + m_{\ell_v} \right]. \tag{3}$$

Here, m_{ℓ_v} is a mask vector whose value is 0 for valid productions $\ell_v \Rightarrow \dots$ and $-\infty$ for all other productions. In practice, we implement e using a linear layer.

Similarly, we can pick variables from the set of variables V in scope using their representations $\mathbf{h}_{v_{nar}}$ (initially the representation obtained from the context, and later the attribute representation of the last node in the graph in which they have been used). Thus, to pick a variable at node v with attributes \mathbf{h}_v , we define

$$\operatorname{pickVariable}(\mathcal{V},\mathbf{h}_v) = \operatorname*{arg\,max}_{var \in \mathcal{V}} P(var \mid \mathbf{h}_v) = \operatorname*{arg\,max}_{var \in \mathcal{V}} k(\mathbf{h}_v,\mathbf{h}_{v_{var}}). \tag{4}$$
 In our implementation, we use a single linear layer for k .

Training & Training Objective The different shapes and sizes of generated expressions complicate an efficient training regime. However, note that given a ground truth target tree, we can easily augment it with all additional edges according to Alg. 2. Given that full graph, we can compute a propagation schedule (intuitively, a topological ordering of the nodes in the graph, starting in the root node) that allows to repeatedly apply (2) to obtain representations for all nodes in the graph. By representing a batch of graphs as one large (sparse) graph with many disconnected components, similar to Allamanis et al. [3], we can train our sequential graph neural network efficiently. We have released the code for this at https://github.com/Microsoft/gated-graph-neural-network-samples.

Our training procedure thus combines an encoder (cf. Sect. 5), whose output is used to initialize the representation of the root and context variable nodes in our augmented syntax graph, the sequential graph propagation procedure described above, and the decoder choice functions (3) and (4). We train the system end-to-end using a maximum likelihood objective.

Additional Improvements Following Rabinovich et al. [19], we provide additional information for Child edges. To allow this, we change our setup so that some edge types also require an additional label, which is used when computing the "messages" sent between different nodes in the graph.

Concretely, we extend (2) by considering sets of unlabeled edges
$$\mathcal{E}_v$$
 and labeled edges \mathcal{E}_v^{ℓ} :
$$\mathbf{h}_v = g(\mathsf{emb}(\ell_v), \sum_{(u_i, t_i, v) \in \mathcal{E}_v} f_{t_i}(\mathbf{h}_{u_i}) + \sum_{(u_i, t_i, \ell_i, v) \in \mathcal{E}_v^{\ell}} f_{t_i}(\mathbf{h}_{u_i}, \mathsf{emb}_e(\ell_i))) \tag{5}$$

Thus for labeled edge types, f_{t_i} takes two inputs and we additionally introduce a learnable embedding for the edge labels. In our experiments, we found it useful to label Child with tuples consisting of the chosen production and the index of the child, i.e., in Fig. 2, we would label the edge from 0 to 3 with (2,0), the edge from 0 to 6 with (2,1), etc.

Furthermore, we have extended pick Production to also take the information about available variables into account. Intuitively, this is useful in cases of productions such as Expr \improx Expr.Length, which can only be used in a well-typed derivation if an array-typed variable is available. Thus, we extend $e(\mathbf{h}_v)$ from (3) to additionally take the representation of all variables in scope into account, i.e., $e(\mathbf{h}_v, r(\{\mathbf{h}_{v_{var}} \mid var \in \mathcal{V}\}))$, where we have implemented r as a max pooling operation.

4 Related Work

The generation of source code has been studied in a wide range of different settings [2]. We focus on the most closely related works in language modeling here. Early works approach the task by generating code as sequences of tokens [11, 12], whereas newer methods have focused on leveraging the known target grammar and generate code as trees [6, 16, 17, 19, 24] (*cf.* Sect. 2 for an overview of the generic method). However, we are not aware of any generative code model that takes the semantics of the partially generated code into account, apart from the contribution of Maddison and Tarlow [16], which consider the scoping rules of the generated code to improve the generation of suitable identifiers. Finally, there is a long traditional of code generation conditioned on noncode modalities. This includes semantic parsing work that generates code based on natural language input [1, 19, 24] and work on program synthesis from input-output examples [17].

We will discuss the differences to the different tree-based generative models in detail, as they are nearest to our work. The methods primarily differ in what information they use to decide which nonterminal expansion rule to use next. Maddison and Tarlow [16] consider the representation of the immediate parent node, and suggest to consider more information (e.g., nearby tokens). Parisotto et al. [17] compute fresh representation of the partial tree at each expansion step using R3NNs (which intuitively perform a leaf-to-root traversal followed by root-to-leaf traversal of the AST). The PHOG [6] model combines a probabilistic context-free grammar with learned (decision tree-style) programs that can be trained to focus on related syntax elements, but again, a purely syntactic view of the code is taken. Rabinovich et al. [19] only use information about the parent node, but use neural networks specialized to different non-terminals to gain more fine-grained control about the flow of information to different successor nodes. Finally, Amodio et al. [4] and Yin and Neubig [24] follow a left-to-right, depth-first expansion strategy, but thread updates to single state (via a gated recurrent unit) through the overall generation procedure, thus giving the pickProduction procedure access to the full generation history as well as the representation of the parent node. Amodio et al. [4] also suggest the use of attribute grammars, but use them to define a deterministic procedure that collects information throughout the generation process, which is provided as additional feature.

As far as we are aware, previous work has not considered a task in which a generative model fills a hole in a program with an expression. The task of Raychev et al. [20] is nearest to our ExprGen, but instead focuses on filling holes in sequences of API calls. There, the core problem is identifying the correct function to call from a potentially large set of functions, given a sequence context. In contrast, ExprGen requires to handle arbitrary code in the context, and then to build possibly complex expressions from a small set of operators. Allamanis et al. [3] consider similar context, but are only picking a single variable from a set of candidates, and thus require no generative modeling.

5 Evaluation

Dataset We have collected a dataset for our ExprGen task from about 200 highly-starred open-source C# projects on GitHub. For this, we parsed all C# files and identified all expressions of the fragment that we are considering (*i.e.*, restricted to numeric, Boolean and string types, or arrays of such values; and not using any user-defined functions). We abstract away uncommon numeric and string literals to special "UNKNUM" and "UNKSTR" tokens to reduce the vocabulary size. This resulted in 102,766 samples overall. Finally, we split the data into a training-validation-test set (60-20-20), keeping all expressions collected from a single source file within a single fold. Samples from our dataset can be found in the appendix.

Encoders To evaluate our decoder and the baseline, we need to pick an encoder for the context information. We considered two models. The first encoder S is a two-layer bi-directional recurrent neural network (using a GRU [7]) to encode the tokens before and after the "hole" in which we want to generate an expression. Additionally, it computes a representation for each variable var in scope in the context in a similar manner: For each variable var it identifies usages before/after the hole and encodes each of them independently using a second bi-directional two-layer GRU, which processes a fixed window of tokens before/after the variable usage. It then computes a representation for var by average pooling the final states of these GRU runs.

The second encoder G is an implementation of the program graph approach introduced by Allamanis et al. [3]. We follow the transformation used for the VarMisuse task presented in that paper, *i.e.*, the

Table 1: Evaluation of encoder and decoder combinations.

program is transformed into a graph, and the target expression is replaced by a fresh dummy node. We then run a graph neural network for 8 steps to obtain representations for all nodes in the graph, allowing us to read out a representation for the "hole" (from the introduced dummy node) and for all variables in context.

Baseline Decoders To compare our model to existing generative models, we consider a range of baselines. The simplest baseline is a recurrent neural network decoder, S (again using a GRU cell), generating one source token at a time. Additionally, we consider a range of ablations of our model, some of which resemble baselines from the literature. First, T is the model described in Sect. 3 using only Child edges without edge labels, corresponding to a simple tree neural network approach with a facility to select variables from scope (essentially, a neural version of the model of Maddison and Tarlow [16]). The second model, Syn, resembles the syntactic neural model introduced by Yin and Neubig [24]. For this, we extend T by a new NextExp edge that connects nodes to each other in the expansion sequence of the tree, thus corresponding to the action flow [24]. The third model, ASN, is similar to the abstract syntax networks by Rabinovich et al. [19], extending the T model by adding edge labels on Child that encode the chosen production and the index of the child (corresponding to the "field name" [19]).

Our baseline models primarily differ from the prior work in two ways: (a) we do not provide an attention mechanism over the input, and (b) the original models from the literature use RNN modules to generate function names and choose arguments from the context [24] and to generate string literals [19]. However, (a) is a limitation shared by all of our decoder models and we expect that such an attention mechanism would improve all models to a similar extent. On the other hand, regarding (b), we believe that our variable selection mechanism pickVariable is superior to the use of copy attention in an RNN generator, and thus improves on the literature. Our ExprGen task limits the set of allowed functions and string literals substantially and thus no RNN decoder generating such things is required, though it could be easily added to our model to handle the more general case.

5.1 Quantitative Evaluation

Metrics We are interested in the ability of a model to generate valid expressions based on the current code context. To evaluate this, we consider five different metrics. As our ExprGen task requires a conditional language model of code, we first consider the per-token perplexity of the model; the lower the perplexity, the better the model fits the real data distribution. We then turn to two metrics that measure how well the models can produce correct code, evaluating how often the resulting expression is syntactically well-formed (*i.e.*, can be parsed by the $C^{\#}$ compiler) and how often it is well-typed (*i.e.*, can be typed in the original code context). We report these metrics for the most likely expression returned by beam search decoding with beam width 5. Finally, we compute how often the ground truth expression was generated (reported for the most likely expression, as well as for the top five expressions). This measure is stricter than semantic equivalence, as an expression j > i will not match the equivalent i < j.

Result Analysis We show the results of our evaluation in Tab. 1. We considered a number of other encoder/decoder combinations (*e.g.*, a plain seq2seq model), but they performed substantially worse than the shown models. Overall, the graph encoder architecture seems to be best-suited for this task. We believe the choice of variables from context to be the limiting factor for the sequence decoder, as we do not use pointer network-style copying. This can be seen in the very high perplexity and low ratio of well-typed expressions in the results for the $\mathcal{G} \to \mathcal{S}$ model.

```

Figure 3: Two lightly edited examples from our test set and expressions predicted by different models. More examples can be found in the appendix.

All models, including the sequence model, learn to generate syntactically valid code (which is relatively simple in our domain). However, the different encoder models perform very differently on semantic measures such as well-typedness and the retrieval of the ground truth expression. The results show a clear trend that correlates better semantic results with the amount of information about the partially generated programs employed by the generative models. Our \mathcal{NAG} model, combining and adding additional signal sources, consequently performs best on all measures.

5.2 Qualitative Evaluation

As the results in the previous section suggest, the proposed ExprGen task is hard even for the strongest models we evaluated, achieving no more than 50% accuracy on the top prediction. It is also unsolvable for classical logico-deductive program synthesis systems, as the provided code context does not form a precise specification. However, we do know that most instances of the task are (easily) solvable for professional software developers, and thus believe that machine learning systems can have considerable success on the task.

Fig. 3 shows two (abbreviated) samples from our test set, together with the predictions made by the two strongest models we evaluated. In the first example, we can see that the $\mathcal{G} \to \mathcal{NAG}$ model correctly identifies that the relationship between paramCount and methParamCount is important (as they appear together in the blocked guarded by the expression to generate), and thus generates comparison expressions between the two variables. The $\mathcal{G} \to \mathcal{ASN}$ model lacks the ability to recognize that paramCount (or any variable) was already used and thus fails to insert both relevant variables. We found this to be a common failure, often leading to suggestions using only one variable (possibly repeatedly). In the second example, both $\mathcal{G} \to \mathcal{NAG}$ and $\mathcal{G} \to \mathcal{S}yn$ have learned the common if (var.StartsWith(...)) { ... var.Substring(num) ... } pattern, but of course fail to produce the correct string literal in the condition. We show results for all of our models for these examples, as well as for as additional examples, in Appendix B.

6 Discussion & Conclusions

We presented a generative code model that leverages known semantics of partially generated programs to direct the generative procedure. The key idea is to augment partial programs to obtain a graph, and then use graph neural networks to compute a precise representation for the partial program. This representation then helps to better guide the remainder of the generative procedure. We have shown that this approach can be used to generate small but semantically interesting expressions

from very imprecise context information. The presented model could be useful in program repair scenarios (where repair proposals need to be scored, based on their context) or in the code review setting (where it could highlight very unlikely expressions). We also believe that similar models could have applications in related domains, *e.g.*, semantic parsing or neural program synthesis.

A Dataset Samples

Below we list some sample snippets from the training set for our ExprGen task. The highlighted expressions are to be generated.

Figure 4: Sample snippet from the Lean project. Formatting has been modified.

Figure 5: Sample snippet from the BotBuilder project. Formatting has been modified.

Figure 6: Sample snippet from the Chocolatey project. Formatting has been modified.

Figure 7: Sample snippet from the Chocolatey project. Formatting has been modified and the snippet has been abbreviated.

```
while ( count >= startIndex )
{
    c = s[count];
    if ( c != ',  && c != 'n' ) break;
    count--;
}
```

Figure 8: Samples snippet in the CommonMark.NET project. Formatting has been modified.

Figure 9: Sample snippet from the Humanizer project. Formatting has been modified.

```
var indexOfEquals = segment.IndexOf('=');
if (indexOfEquals == -1) {
   var decoded = UrlDecode(segment, encoding);
   return new KeyValuePair<string, string>(decoded, decoded);
}
```

Figure 10: Samples snippet from the Nancy project. Formatting has been modified.

Figure 11: Sample snippet from the OpenLiveWriter project. Formatting has been modified.

```
char c = html[j];
if ( c == ';' || (!(c >= 'a' && c <= 'z') && !(c >= 'A' && c <= 'Z') && !(c >= '0' && c <= '9')) )
{
    break;
}</pre>
```

Figure 12: Sample snippet from the OpenLiveWriter project. Formatting has been modified.

```
string entityRef = html.Substring(i + 1, j - (i + 1));
```

Figure 13: Sample snippet from the OpenLiveWriter project. Formatting has been modified.

B Sample Generations

On the following pages, we list some sample snippets from the test set for our ExprGen task, together with suggestions produced by different models. The highlighted expressions are the ground truth expression that should be generated.

```
if (context.Context == _MARKUP_CONTEXT_TYPE.CONTEXT_TYPE_Text &&
           !String.IsNullOrEmpty(text)) {
          originalText.IndexOf(text)
   if (idx == 0) {
       // Drop this portion from the expected string
       originalText = originalText.Substring(text.Length);
       // Update the current pointer
       beginDamagePointer.MoveToPointer(currentRange.End);
   else if (idx > 0 \&\&
      originalText.Substring(0, idx)
           .Replace("\r\n", string.Empty).Length == 0)
   {
       // Drop this portion from the expected string
       originalText = originalText.Substring(text.Length + idx);
       // Update the current pointer
       beginDamagePointer.MoveToPointer(currentRange.End);
   }
   else
   {
       return false;
   }
```

Sample snippet from OpenLiveWriter. The following suggestions were made:
